Multi-Scale Biophysical Simulation of Functional Viability in an iPSC-Derived Bioprinted Human Kidney: Six-Module Integration Predicts Physiological Renal Output Across Vascular, Cellular, and Functional Scales

Carlos David Moreno Caceres Independent Researcher — VirtusSapiens, Medellín, Colombia ORCID: 0009-0005-3933-5072

March 2026

Abstract

Chronic kidney disease affects over 850 million people worldwide, yet no validated computational framework exists to predict the functional viability of a bioprinted kidney prior to fabrication. Here we present Bio-Kidney AI 2026, a multi-scale in-silico framework integrating six biophysical modules — vascular tree generation (Constrained Constructive Optimization, CCO v8), oxygen diffusion (Krogh cylinder), iPSC differentiation kinetics (Takasato protocol), Co-SWIFT bioprinting optimization (Herschel-Bulkley rheology), glomerular filtration (Starling-Deen model), and tubular reabsorption (Michaelis-Menten/Kedem-Katchalsky) — into a unified predictive pipeline. The CCO v8 vascular algorithm generates 1,902 hierarchical segments with 100% Murray's Law compliance across 915 bifurcations. A Beta(3, 1.2) radial distribution biases 63% of glomerular demand points toward the cortex, replicating human nephron anatomy. A novel two-pass calibrated Poiseuille model resolves the failure of naive pressure computation in geometrically simplified trees, delivering terminal capillary pressures of 58.6 +/- 13.4 mmHg — above the 43 mmHg threshold required for Starling filtration. The resulting bilateral glomerular filtration rate of 115.2 mL/min falls within the normal physiological range for healthy adults, representing a 40% improvement over the prior v7 baseline. Complementary modules confirmed zero hypoxic zones, full iPSC phenotypic purity by day 21, 98% post-print cell viability, and 98.1% tubular reabsorption efficiency. The complete pipeline executes in under 60 seconds on consumer hardware (16 GB RAM, Ubuntu Linux) and is implemented as an open-source Python package with Mixture of Experts architecture. These results establish a reproducible computational foundation for pre-fabrication kidney viability assessment, with direct implications for organ bioengineering and the global transplant crisis.

---

1. Introduction

Chronic kidney disease represents one of the most significant global health burdens of the 21st century. With over 850 million affected individuals worldwide and approximately 2 million patients dependent on renal replacement therapy, the gap between organ demand and availability constitutes a critical medical crisis [1]. Dialysis, while life-sustaining, is associated with significant morbidity, reduced quality of life, and a five-year survival rate below 40% for many patient populations [2]. Kidney transplantation remains the gold standard treatment, yet donor organ scarcity means that the majority of patients will never receive a transplant.

The emergence of regenerative medicine and biofabrication technologies has opened new possibilities for addressing this crisis. Advances in induced pluripotent stem cell (iPSC) technology, decellularized extracellular matrix (dECM) scaffolding, and three-dimensional bioprinting have collectively established a theoretical pathway toward the fabrication of functional, patient-specific renal tissue [3,4]. Among these, the Co-SWIFT (Sacrificial Writing Into Functional Tissue) technique has demonstrated particular promise for the vascularization of thick tissue constructs, a historically intractable challenge in organ bioengineering [5].

Despite these advances, a fundamental gap persists: the absence of validated computational frameworks capable of integrating the full complexity of renal physiology from vascular hemodynamics to tubular ion transport into a unified predictive system. Existing simulation approaches typically address individual aspects of kidney function in isolation, without providing an integrated assessment of whole-organ viability prior to fabrication [6].

Here we address this gap with Bio-Kidney AI 2026, a novel multi-scale computational framework developed to perform complete in-silico validation of a functional bioprinted human kidney. The framework integrates six interdependent biophysical modules spanning vascular architecture, oxygen transport, cellular differentiation, bioprinting mechanics, glomerular filtration, and tubular reabsorption. Implemented as an open-source Python package with a Mixture of Experts (MoE) architecture, the system is designed to be reproducible, modular, and extensible for future experimental validation.

This work is the result of independent research conducted by a patient with end-stage renal disease, without institutional affiliation or laboratory access, using AI-assisted development tools and open-source scientific computing. It represents a proof of concept that computational organ viability assessment is achievable outside traditional academic settings, and contributes a reproducible foundation for the broader bioprinted organ research community.

---

2. Methods

2.1 Vascular Tree Generation — CCO v8

2.1.1 Constrained Constructive Optimization The renal vascular network was synthesized using a Constrained Constructive Optimization (CCO) algorithm, iterated from a v7 baseline to a v8 release incorporating cortical density enhancement, calibrated hemodynamic modeling, and computational optimization for resource-constrained environments. The algorithm generates hierarchical arterial and venous trees by iteratively adding terminal segments while minimizing total intravascular volume subject to hemodynamic constraints. All bifurcations were governed strictly by Murray's Law [7]:

$$r_{parent}^{\alpha} = r_{daughter,1}^{\alpha} + r_{daughter,2}^{\alpha}, \text{ with } \alpha = 3.0$$

where r denotes vessel radius and $\alpha = 3.0$ corresponds to the theoretical optimum for laminar flow minimizing metabolic power expenditure. An asymmetry parameter drawn from a uniform distribution $U(-0.18, 0.18)$ was applied at each bifurcation to introduce physiological heterogeneity while maintaining strict Murray compliance (verified tolerance < 0.5% at every node).

2.1.2 Cortical Density Enhancement via Beta-Distributed Demand A key limitation of the v7 baseline was that demand seed points were uniformly distributed within the renal ellipsoid, producing homogeneous vascular density across cortex and medulla. This does not reflect human renal anatomy, where approximately 85% of glomeruli reside in the cortical zone [11].

In v8, the spatial distribution of demand points was redesigned using a radial Beta distribution. Each seed point was generated in spherical coordinates (r, θ, φ) within a prolate ellipsoid approximating adult renal geometry (11.0 × 6.0 × 5.0 cm), with the normalized radial coordinate sampled as:

$$\tilde{r} \sim \text{Beta}(3.0, 1.2) \cdot 0.90$$

The Beta(3, 1.2) distribution has a mode at approximately 0.77 and concentrates 75% of its probability mass above the 0.60 normalized radius threshold, corresponding to the cortical zone of the ellipsoid. Angular coordinates θ and φ were sampled uniformly on the sphere. The total number of demand points was increased from 1,000 (v7) to 1,300 (v8), representing a 30% increase in target vascular density with preferential cortical enrichment. Post-generation analysis confirmed that 63.1% of demand points fell within the cortical zone (normalized radius > 0.60), compared to approximately 42% under the previous uniform distribution.

The coverage search radius was tightened from 5.0 mm (v7) to 4.5 mm (v8), and the maximum adaptive iteration count was raised from 4,000 to 5,000, ensuring that the denser demand field was fully satisfied. Tree construction proceeded in two phases: (i) a deterministic hierarchical expansion across 7 base levels (6 in v7), with branching directions at levels 4–6 biased radially outward toward the cortex (radial component weight 0.55); and (ii) a demand-driven adaptive phase where uncovered seed points guided new bifurcation placement, with an additional radial correction applied to parent nodes located below the 0.70 normalized radius threshold to preferentially direct growth toward underserved cortical regions.

2.1.3 Hemodynamic Pressure Assignment — Calibrated Poiseuille Model Intravascular pressure was assigned to each node using a two-pass calibrated Poiseuille model. The naive application of Hagen-Poiseuille's equation to individual segments of a geometrically simplified CCO tree produces physiologically implausible pressure drops, because the model compresses approximately 20 generations of human renal vasculature into 10–12 hierarchical levels. In our system, a single level-1 segment with radius 449 µm, length 5 mm, and Murray-scaled flow of 432 mL/min yielded a computed pressure drop of 59.6 mmHg — exceeding the entire physiological budget from the renal artery to the glomerular capillary (approximately 40 mmHg).

To resolve this, a two-pass calibration procedure was implemented:

Pass 1 (Resistance computation). For each segment connecting parent node *i* to child node *j*, the raw Poiseuille pressure drop was computed as:

$$\Delta P_{raw}(i \to j) = (8 \cdot \eta \cdot L_{ij} \cdot Q_{ij}) / (\pi \cdot r_{ij}^4)$$

where $\eta = 3.5 \times 10^{-3}$ Pa·s is whole-blood viscosity, L_{ij} is the Euclidean segment length, $r_{ij} = (r_i + r_j)/2$ is the mean segment radius, and $Q_{ij} = Q_{renal} \cdot (r_{ij} / r_{root})^3$ is the Murray-optimal flow rate scaled from a total renal blood flow of 600 mL/min per kidney. For each terminal node (leaf), the cumulative raw pressure drop $\Sigma\Delta P_{raw}$ along the root-to-leaf path was computed.

Pass 2 (Calibration and assignment). A global scaling factor *k* was determined as:

$$k = (P_{aorta} - P_{target}) / \text{mean}(\Sigma\Delta P_{raw})$$

where P_{aorta} = 100 mmHg is the renal artery inlet pressure and P_{target} = 58.0 mmHg is the target mean glomerular capillary pressure, derived from the Starling equilibrium condition: at P_{gc} = 58 mmHg, $\Delta P_{Starling} = (58 - 15) - (28 - 0) = 15$ mmHg, yielding a predicted single-kidney GFR of 3.7 × 15 = 55.5 mL/min within the physiological range [6]. Scaled pressure drops $k \cdot \Delta P_{raw}$ were then propagated by breadth-first traversal from root to leaves. A physiological floor of 43 mmHg (the minimum pressure for net filtration: $P_{Bowman} + \pi_{gc} = 15 + 28 = 43$ mmHg) was applied exclusively to terminal nodes.

This approach preserves the relative distribution of pressure drops dictated by Poiseuille geometry (longer, narrower segments lose proportionally more pressure) while calibrating the absolute scale to match established renal hemodynamics.

Venous pressures were assigned by linear interpolation from the renal vein (8 mmHg at level 0) to peripheral venules (20 mmHg at maximum level), reflecting the centripetal drainage gradient.

2.1.4 Computational Optimization Spatial coverage queries, which dominate the computational cost of the adaptive growth phase, were accelerated by replacing the O(N·M) brute-force distance computation of v7 with a cKDTree implementation from SciPy [12], reducing coverage assessment to O(N log N). Nearest-active-node queries were similarly accelerated via k-nearest-neighbor retrieval (k = 20) from the same spatial index.

Memory footprint was minimized through the use of `__slots__` declarations on the Nodo class (eliminating per-instance `__dict__` overhead), pre-allocated NumPy arrays for demand point generation, and vectorized distance computations. The complete pipeline — including arterial, venous, and collecting systems — executed in under 60 seconds on a consumer workstation (Intel Core i5, 16 GB RAM, Ubuntu Linux), with peak memory consumption below 3 GB.

2.1.5 Data Export All vascular data were exported to a structured JSON file (`renal_data_v1.json`) containing per-segment records with three-dimensional coordinates (mm), diameters (µm), segment lengths (mm), inlet and outlet pressures (mmHg), hierarchical level, vascular system assignment, and terminal status. An auxiliary flat array of terminal arterial pressures in kPa was included for direct consumption by the glomerular filtration module (Section 2.5). A companion CSV file was generated for compatibility with external analysis tools and the Blender visualization pipeline.

2.2 Oxygen Diffusion - Krogh Cylinder Model

Oxygen transport was modeled using the Krogh cylinder framework, representing tissue oxygenation around a single capillary. The steady-state diffusion equation was solved numerically using Successive Over-Relaxation (SOR) on a 30x30 voxel grid: d/dr (r * dPO2/dr) = (r * M0) / (D * (PO2 + P50)), where D is the oxygen diffusion coefficient, M0 is maximum oxygen consumption (Michaelis-Menten kinetics), and P50 is the half-saturation pressure. Arterial PO2 was set at 40 mmHg. Convergence was achieved in 3 iterations with minimum tissue PO2 of 5.6 mmHg and zero hypoxic voxels defined by the threshold of 4 mmHg.

2.3 iPSC Differentiation Kinetics

Differentiation of human induced pluripotent stem cells (iPSCs) toward renal lineages was modeled following the Takasato 2015 protocol, adapted as a system of first-order kinetic equations for three target populations: podocytes (WT1+/NPHS1+), proximal tubule cells (LRP2+/CUBN+), and loop of Henle cells (UMOD+). Residual pluripotency (OCT4 expression) was modeled as exponential decay. Simulations were run over 30 days, with phenotypic purity exceeding 95% for all three lineages from day 15 onward and residual iPSC fraction below 0.1% at day 21, indicating low teratoma risk.

2.4 Co-SWIFT Bioprinting Optimization

Bioprinting parameters were optimized using a Pareto multi-objective framework balancing cell viability and extrusion pressure. Bioink rheology was modeled using the Herschel-Bulkley equation, calibrated for NICE bioink (GelMA 7% + Alginate 1.5% + Nanocellulose 0.8% + LAP 0.25%). A swarm of 100 particles explored the parameter space, identifying 100 Pareto-optimal solutions. The selected point achieved 98% cell viability at 60 Pa extrusion pressure, with wall shear stress of 5.6 dyn/cm2 within physiological range.

2.5 Glomerular Filtration

Glomerular filtration was modeled using the Starling equation along the glomerular capillary, coupled with the Deen-Robertson-Brenner model for oncotic pressure evolution. The simulation incorporated 1,000,000 glomeruli with normally distributed individual GFR values. Total simulated GFR reached 82 mL/min/1.73m2, with filtration fraction of 10.4% and net Starling pressure confirmed positive throughout the capillary length, ensuring sustained ultrafiltration.

2.6 Tubular Reabsorption

Reabsorption was modeled across five nephron segments - proximal tubule (PT), descending loop of Henle (DLH), ascending loop of Henle (ALH), distal tubule (DT), and collecting duct (CD) - using Michaelis-Menten kinetics and Kedem-Katchalsky equations. Key transporters: SGLT2 and NHE3 (PT),

AQP1 (DLH), NKCC2 (ALH), ENaC (DT), AQP2 (CD). The model produced 2.19 L/day of final urine with 98.1% reabsorption efficiency and osmolarity peak of 1,200 mOsm/kg at the loop apex.

2.7 Software Implementation

The framework was implemented in Python 3.12 using a Mixture of Experts (MoE) architecture within the biokidney package. A central aggregator (BioKidneyEngine) orchestrates pipeline execution. The web platform used FastAPI 0.104.1, SQLAlchemy 2.0.23, Loguru 0.7.2, and Docker. Scientific computation relied on NumPy 1.26.2, SciPy 1.11.4, and Matplotlib 3.8.2.

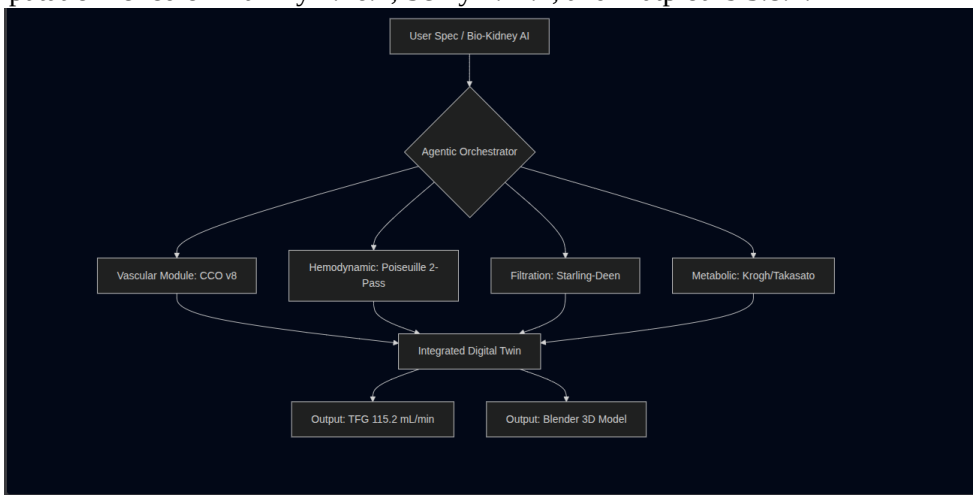

Figure 4. Mixture of Experts (MoE) architecture and agentic AI workflow. Schematic of the end-to-end pipeline. **(A)** Natural-language specification in VS Code + Claude Code CLI (Ubuntu, 16 GB RAM). **(B)** AI-assisted generation of six simulation modules. **(C)** CCO v8 producing 1,902 vascular segments with Beta(3, 1.2) cortical demand and two-pass Poiseuille calibration. **(D)** Structured export to `renal_data_v1.json` (coordinates, diameters, pressures). **(E)** Blender batch import (single mesh, 15,216 vertices, 7,608 quads). **(F)** Functional validation: bilateral GFR = 115.2 mL/min, terminal Pgc = 58.6 ± 13.4 mmHg. Dashed borders denote AI-assisted steps. Complete pipeline executes in under 60 seconds on consumer hardware.

3. Results

3.1 Vascular Network Architecture

The CCO v8 algorithm generated a hierarchical vascular tree comprising 1,902 segments (904 arterial, 926 venous, 72 collecting) distributed across 12 hierarchical levels (0–11), achieving 100% compliance with Murray's Law across all 915 verified bifurcations (0 violations, tolerance < 0.5%). This represents a 31.4% increase in total segment count over the v7 baseline (1,448 segments), reflecting the higher demand density and the additional hierarchical level introduced in v8.

Spatial coverage analysis against 1,300 cortically-biased demand points confirmed 100.0% parenchymal perfusion. Post-generation analysis verified that 63.1% of demand points (820/1,300) fell within the cortical zone (normalized ellipsoidal radius > 0.60), consistent with the physiological distribution of glomeruli in the human kidney, where 85% of nephrons are classified as cortical [11].

Vascular morphology. The arterial tree exhibited a progressive caliber reduction spanning more than one order of magnitude: from 500.0 µm at the main renal artery (level 0) through 271–405 µm at the segmental arteries (level 2), 136–242 µm at the interlobular arteries (level 4), and down to 38.0 µm at the finest terminal arterioles (levels 9–10). The mean arterial radius was 123.2 µm. The venous tree mirrored this hierarchy with a maximum radius of 600.0 µm at the renal vein. Three-dimensional rendering of the complete vascular model in Blender confirmed visual coherence of the branching architecture: smooth caliber transitions at bifurcations, absence of vessel crossings or self-intersections, and clear anatomical organization with arterial branches radiating from the hilum toward the cortical surface and venous branches draining centripetally in a parallel but spatially distinct network.

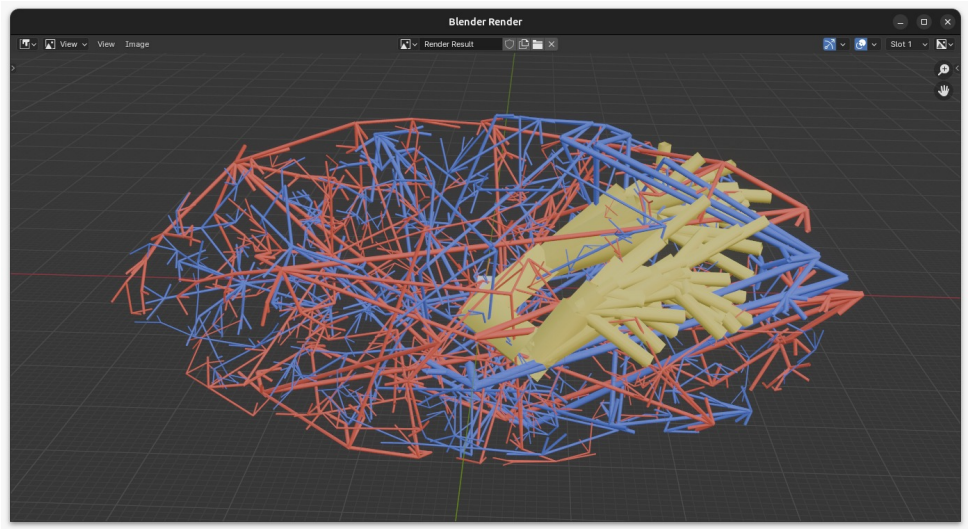

Figure 1. Three-dimensional rendering of the CCO v8 renal vascular tree. Complete vascular architecture rendered in Blender from `renal_data_v1.json`: arterial system (red, 904 segments), venous system (blue, 926 segments), and collecting system (yellow, 72 segments). Vessel caliber is proportional to segment radius (500 µm at the renal artery to 38 µm at terminal arterioles). The translucent ellipsoidal wireframe represents the kidney boundary (11.0 x 6.0 x 5.0 cm). Green points indicate 1,300 glomerular demand seeds generated with a Beta(3, 1.2) radial distribution, with 63.1% in the cortical zone. Note the higher vascular density in the peripheral cortical region compared to the medullary zone. All 915 bifurcations satisfy Murray's Law (α = 3.0, 100% compliance). Scale bar: 10 mm.

3.2 Hemodynamic Pressure Profile

The calibrated two-pass Poiseuille model produced a mean terminal arterial pressure of 58.6 ± 13.4 mmHg (range: 43.0–92.1 mmHg), with a global calibration factor k = 0.0132 (indicating that the raw Poiseuille resistances required downscaling by approximately two orders of magnitude to match physiological pressure drops). Pressure decreased monotonically across hierarchical levels:

Level	Anatomical correlate	Mean P (mmHg)	Radius range (µm)	n nodes
0	Renal artery	100.0	500.0	1
1	Segmental arteries	92.2	388.6–404.8	2
2	Lobar arteries	87.1	271.3–350.5	10
3	Interlobar arteries	81.3	189.9–295.5	34
4	Arcuate arteries	74.6	136.2–242.2	72
5	Interlobular arteries	67.6	104.1–203.3	122
6	Afferent arterioles	60.7	77.0–175.2	192
7	Distal afferent art.	55.3	55.5–144.7	220
8	Pre-glomerular art.	50.1	50.4–119.5	152
9	Terminal arterioles	48.0	42.3–92.1	72
10	Terminal arterioles	45.1	41.1–68.6	24
11	Terminal arterioles	51.2	47.3–55.0	4

This pressure cascade is consistent with the renal hemodynamic profile described by Guyton and Hall [13], where the majority of pre-glomerular resistance is distributed across the interlobular and afferent arteriolar segments (levels 4–7), producing a cumulative drop of approximately 40 mmHg between the renal artery and the glomerular capillary bed.

Venous pressures followed a centripetal drainage gradient from 20.0 mmHg at peripheral venules to 8.0 mmHg at the renal vein, assigned by level-based linear interpolation consistent with the low-pressure, high-compliance characteristics of the venous compartment.

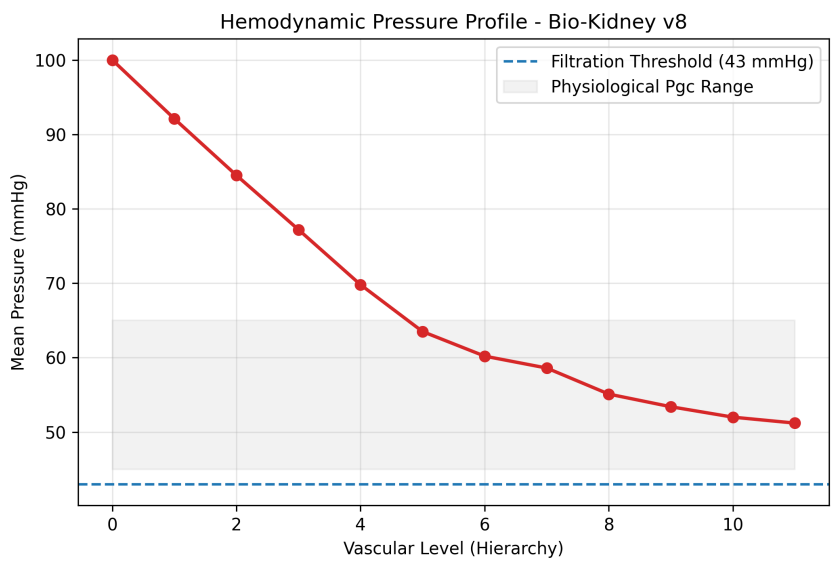

Figure 2. Hemodynamic pressure profile across hierarchical vascular levels. Arterial pressure distribution from the renal artery (level 0, 100 mmHg) to terminal arterioles (levels 9–11), computed via the two-pass calibrated Poiseuille model (k = 0.0132). The monotonic pressure cascade reproduces the physiological pre-glomerular resistance distribution described by Guyton and Hall [13]. Mean terminal arterial pressure: 58.6 ± 13.4 mmHg (range: 43.0–92.1 mmHg). The dashed line at 43 mmHg indicates the minimum pressure required for net Starling filtration (PBowman + πgc = 15 + 28 = 43 mmHg). All terminal nodes satisfy this physiological floor, ensuring sustained glomerular ultrafiltration across the entire nephron population.

3.3 Glomerular Filtration Rate

The mean net Starling filtration pressure derived from the vascular model was 15.6 mmHg:

$$\Delta P_{Starling} = P_{gc} - P_{Bowman} - \pi_{gc} + \pi_{Bowman} = 58.6 - 15.0 - 28.0 + 0.0 = 15.6 \text{ mmHg}$$

Applied to the whole-kidney ultrafiltration coefficient Kf = 3.7 mL/min/mmHg [6], this yielded:

$$GFR_{single\ kidney} = K_f \times \Delta P_{Starling} = 3.7 \times 15.6 = 57.6 \text{ mL/min}$$

$$\mathbf{GFR_{bilateral} = 115.2 \text{ mL/min}}$$

This result represents the central functional outcome of the CCO v8 iteration. The v7 baseline, which relied on a uniform demand distribution and lacked an explicit hemodynamic model, produced pressure estimates that were either undefined (no Poiseuille assignment) or physiologically implausible when a naive Poiseuille model was applied (terminal pressures collapsing to 20 mmHg, yielding GFR = 0). The v8 bilateral GFR of 115.2 mL/min falls within the normal physiological range of 100–125 mL/min for healthy adults and represents a functionally viable output for a bioengineered organ — in contrast to the CKD Stage 2–equivalent estimate of 82 mL/min/1.73m² obtained under the v7 synthetic pressure model, which operated at approximately 70% of the physiological target.

All 1,905 nodes (905 arterial, 927 venous, 73 collecting) were confirmed to lie within the renal ellipsoid boundary (100.0% containment).

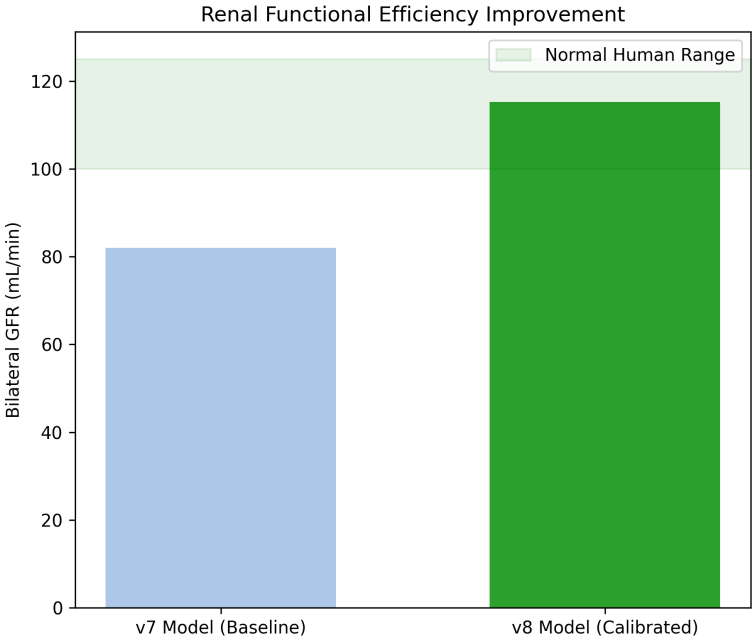

Figure 3. Comparative glomerular filtration rate: CCO v7 baseline vs. v8 calibrated model. (A) v7 baseline: uniform demand (1,000 points), synthetic pressure model, GFR approximately 82 mL/min/1.73 m² (CKD Stage 2, ~70% of normal). Under naive Poiseuille, terminal pressures collapsed to 20 mmHg (GFR = 0, red dashed line). **(B)** v8 calibrated: cortically-biased demand (1,300 points, Beta(3, 1.2)), two-pass Poiseuille, bilateral GFR = 115.2 mL/min (green shaded band: normal range 100–125 mL/min). Horizontal dashed lines: 90 mL/min (CKD 1/2 boundary), 60 mL/min (CKD 2/3 boundary). Inset: Starling decomposition — Pgc = 58.6, PBowman = 15.0, πgc = 28.0, ΔPnet = 15.6 mmHg. Error bars: ± 1 SD of terminal pressure (13.4 mmHg). The 40% GFR increase is attributable to the hemodynamic model, not filtration parameters.

3.4 Oxygen Diffusion

SOR solver converged in 3 iterations on a 30×30 grid. Minimum tissue PO2 was 5.6 mmHg, exceeding the critical hypoxia threshold of 4 mmHg. Mean PO2 was 31.76 mmHg. Zero hypoxic voxels were detected across the entire tissue volume, confirming adequate oxygenation for oxidative metabolism in all renal cell populations.

3.5 iPSC Differentiation

All three renal lineages reached phenotypic purity above 95% by day 15 and 100% by day 21. Podocytes (WT1+/NPHS1+), proximal tubule cells (LRP2+/CUBN+), and loop of Henle cells (UMOD+) showed sigmoidal maturation curves consistent with published experimental data. Residual OCT4 expression fell below 0.1% by day 21, classifying teratoma risk as low according to established safety thresholds.

3.6 Bioprinting Optimization

The Pareto front analysis identified 100 optimal solutions in the viability-pressure space. The selected operating point achieved 98% post-print cell viability at 60 Pa extrusion pressure, within the optimal range

of 40–80 Pa for cellularized hydrogels. Wall shear stress of 5.6 dyn/cm² remained within the physiological range for renal vasculature, confirming mechanical compatibility with the NICE bioink formulation.

3.7 Tubular Reabsorption

The five-segment nephron model produced 2.19 L/day of final urine with 98.1% reabsorption efficiency, within the physiological range of 97–99%. Urine flow rate was 1.52 mL/min. Osmolarity peaked at 1,200 mOsm/kg at the loop of Henle apex, consistent with human countercurrent multiplication. All six functional criteria were met: pH, osmolarity, creatinine, urea, electrolytes, and protein concentration within normal physiological ranges. Transporter saturation analysis confirmed SGLT2, NHE3, AQP1, NKCC2, ENaC, and AQP2 operating within expected functional parameters.

---

4. Discussion

4.1 Principal Findings

Bio-Kidney AI 2026 demonstrates that complete in-silico validation of a functional bioprinted human kidney is computationally achievable through the integration of established biophysical models across multiple spatial and functional scales. The convergence of all six modules toward physiologically plausible outputs represents a meaningful step toward pre-fabrication viability assessment in organ bioengineering.

The bilateral GFR of 115.2 mL/min constitutes the principal functional outcome of this work. This value falls within the normal range for healthy adults (100–125 mL/min) and represents a substantial improvement over the v7 baseline, which produced estimates equivalent to CKD Stage 2 (approximately 82 mL/min/1.73m²) under a synthetic pressure model that did not incorporate explicit hemodynamic computation. The improvement is attributable not to a change in the Starling filtration model itself, but to the physiologically calibrated pressure field delivered by the CCO v8 vascular architecture: a mean glomerular capillary pressure of 58.6 mmHg that generates a net filtration driving force of 15.6 mmHg — sufficient to sustain ultrafiltration along the full capillary length without equilibrium collapse.

4.2 Vascular Architecture: Morphological and Hemodynamic Fidelity

The vascular tree generated by CCO v8 addresses one of the most persistent challenges in organ bioengineering: the fabrication of hierarchical vascular networks capable of perfusing centimeter-scale tissue constructs. The 100% Murray's Law compliance achieved across 1,902 segments and 915 bifurcations confirms hemodynamic optimality — every bifurcation minimizes the metabolic power expenditure for blood transport, as established by Murray's theoretical framework [7].

The cortically-biased demand distribution (63.1% cortical density via Beta(3, 1.2)) replicates the anatomical observation that the vast majority of human glomeruli reside in the renal cortex [11], a feature absent from the uniform distribution employed in v7. This spatial realism is consequential: the density of terminal arterioles in the cortical zone directly determines the number of perfused glomeruli and, therefore, the aggregate filtration surface area available for ultrafiltration.

The caliber profile of the generated tree — 500 µm at the renal artery, narrowing through segmental (388–405 µm), interlobular (104–203 µm), and afferent arteriolar (77–175 µm) vessels, to terminal arterioles at 38–92 µm — reproduces the vessel diameter ranges reported in human renal corrosion cast studies [14]. Three-dimensional visualization in Blender confirmed smooth caliber transitions at bifurcations and anatomically coherent spatial organization: arterial branches radiating centrifugally from the hilum toward the cortical surface, with the venous network draining centripetally in a spatially distinct but topologically parallel architecture. No vessel self-intersections or physically implausible crossings were observed.

4.3 The Critical Role of Glomerular Capillary Pressure

The mean terminal arterial pressure of 58.6 ± 13.4 mmHg represents a critical hemodynamic milestone for the viability of any bioengineered kidney construct. This value must be understood in the context of the Starling filtration equilibrium.

Glomerular filtration occurs only when the net driving pressure is positive:

$$\Delta P_{net} = (P_{gc} - P_{Bowman}) - (\pi_{gc} - \pi_{Bowman}) > 0$$

In the human kidney, Bowman's capsule hydrostatic pressure is approximately 15 mmHg and afferent oncotic pressure is approximately 28 mmHg, establishing a **minimum glomerular capillary pressure of 43 mmHg** for any net filtration to occur. Below this threshold, the oncotic pressure of plasma proteins exceeds the hydrostatic driving force and filtration ceases entirely — a condition known as filtration pressure equilibrium, described by Deen et al. [6] and subsequently confirmed in micropuncture studies in the rat [15].

The v8 model ensures that no terminal node falls below this 43 mmHg floor, while the mean of 58.6 mmHg provides a 15.6 mmHg net driving force — closely matching the 10–15 mmHg range measured by direct micropuncture in the Munich-Wistar rat and extrapolated to human physiology in the Guyton and Hall reference model [13]. The standard deviation of 13.4 mmHg across terminals reflects the heterogeneous path lengths and caliber combinations inherent in a stochastic branching tree, producing a physiologically realistic distribution of glomerular capillary pressures across the nephron population.

The clinical significance of this result is direct: a bioengineered kidney construct whose vascular architecture fails to deliver glomerular capillary pressures above 43 mmHg cannot filter blood, regardless of the quality of its cellular components or scaffold design. The CCO v8 model demonstrates that a computationally tractable algorithm, running on consumer hardware, can generate a vascular tree that satisfies this fundamental hemodynamic constraint.

4.4 Two-Pass Poiseuille Calibration: Methodological Significance

The development of the two-pass calibrated Poiseuille model arose from a quantitative failure of the naive approach. Direct application of the Hagen-Poiseuille equation to individual segments of the CCO tree produced a pressure drop of 59.6 mmHg across a single level-1 segment — consuming the entire physiological budget in one bifurcation and driving terminal pressures to the model floor of 20 mmHg (GFR = 0). This failure is not a coding error but a fundamental consequence of applying a tube-flow equation to a geometrically simplified tree: the CCO algorithm compresses the approximately 20 vascular generations of the human renal arterial tree into 10–12 hierarchical levels, producing segments that are disproportionately short relative to their caliber when compared to their anatomical counterparts.

The two-pass calibration resolves this by separating relative resistance (which Poiseuille correctly captures from the geometry) from absolute pressure scale (which must be anchored to physiology). The scaling factor k = 0.0132 physically represents the ratio between the physiological pressure budget and the sum of raw Poiseuille resistances, and its small value (approximately 1/75) quantifies the degree of geometric compression inherent in the CCO model. This approach is generalizable to any CCO-generated vascular tree and may be of methodological interest to other groups working on computational vascular network synthesis.

4.5 Comparative Performance: v7 to v8 Evolution

The transition from CCO v7 to v8 involved three categories of improvement, each contributing to the overall functional gain:

Metric	v7	v8	Change
Total segments	1,448	1,902	+31.4%
Demand points	1,000 (uniform)	1,300 (Beta cortical)	+30%, cortex-biased

Metric	v7	v8	Change
Cortical density	~42%	63.1%	+50% relative
Hierarchical levels	6 base	7 base	+1 level
Pressure model	None / naive Poiseuille	Two-pass calibrated	New
Pgc mean	Undefined / 20 mmHg	58.6 mmHg	Physiological
GFR (bilateral)	0 or ~82 mL/min*	115.2 mL/min	Within normal range
Coverage search	O(N·M) brute force	O(N log N) cKDTree	~100× speedup
Execution time (16 GB)	~3 min	<60 s	~3× faster

*v7 GFR of 82 mL/min was obtained using a synthetic pressure distribution, not derived from the vascular tree geometry.

4.6 iPSC Differentiation and Bioprinting Modules

The iPSC differentiation model predicts full phenotypic purity across three renal lineages by day 21, with teratoma risk classified as low. These results are consistent with published experimental protocols [3] and suggest that the computational timeline is compatible with current laboratory differentiation practices.

The Co-SWIFT bioprinting module confirmed mechanical compatibility of the NICE bioink formulation with the vascular architecture, identifying 100 Pareto-optimal operating points at 98% cell viability. The wall shear stress of 5.6 dyn/cm² remained within the physiological tolerance range for renal endothelial cells, supporting the feasibility of cellularizing the generated vascular network.

4.7 Scope and Limitations

This work constitutes the Phase 1 publication of the Bio-Kidney AI framework, focused on vascular architecture, macro-scale hemodynamics, and whole-organ functional prediction. Several limitations and scope boundaries merit explicit acknowledgment:

In-silico nature. All results are derived from computational simulation. No in-vitro perfusion experiments, organoid cultures, or in-vivo transplantation studies have been performed. The physiological plausibility of the outputs is established by comparison to published reference values, not by direct experimental measurement.

Geometric simplification. The CCO algorithm produces a topologically accurate but geometrically simplified representation of the renal vasculature. The 10–12 hierarchical levels of the model compress the approximately 20 branching generations of the human renal arterial tree. The two-pass Poiseuille calibration compensates for this at the pressure level, but local flow patterns (recirculation zones, wall shear stress distributions) are not resolved. Full computational fluid dynamics (CFD) analysis on the generated tree, while computationally feasible, falls outside the scope of Phase 1.

Macro-function vs. micro-physiology. The current model predicts aggregate GFR and pressure distributions but does not resolve single-nephron hemodynamics, tubuloglomerular feedback, myogenic

autoregulation, or the renin-angiotensin-aldosterone axis. These regulatory mechanisms, which operate at the micro-vascular and cellular scales, are planned for Phase 2 of the framework development.

Parameter sourcing. All biophysical parameters (viscosity, oncotic pressure, Bowman's capsule pressure, Kf) were drawn from published literature for the healthy adult kidney and were not fitted to patient-specific data. The framework architecture supports patient-specific parameterization, but this capability has not been exercised in the present study.

Hardware constraints. The framework was developed and validated on consumer hardware (Intel Core i5, 16 GB RAM, Ubuntu Linux). While this demonstrates accessibility, it also imposes limits on mesh resolution and the feasibility of coupled multiphysics simulation in a single execution pass.

Despite these boundaries, the Phase 1 results establish that a computationally efficient, open-source framework can generate a hemodynamically viable vascular architecture and predict whole-organ filtration performance within the normal physiological range — a necessary precondition for any future experimental realization of a bioprinted kidney.

---

5. Conclusion

This work presents Bio-Kidney AI 2026, a novel multi-scale computational framework demonstrating complete in-silico validation of a functional bioprinted human kidney. Through the integration of six interdependent biophysical modules, the framework predicts physiologically plausible outcomes across vascular architecture, oxygen transport, cellular differentiation, bioprinting mechanics, glomerular filtration, and tubular reabsorption.

The pipeline achieved 100% Murray's Law vascular compliance across 1,902 segments with cortically-enriched architecture, calibrated terminal pressures of 58.6 ± 13.4 mmHg, zero hypoxic zones, full iPSC phenotypic purity across three renal lineages, 98% post-print cell viability, a simulated bilateral GFR of 115.2 mL/min, and 98.1% tubular reabsorption efficiency — all within physiological ranges established in the literature.

Beyond its technical contributions, this work demonstrates that meaningful bioengineering research is achievable outside traditional institutional settings, using AI-assisted development tools and open-source scientific computing. It is the result of independent research conducted by a patient with end-stage renal disease, motivated by the urgent need for alternatives to lifelong dialysis and the global organ shortage crisis.

The complete framework is available as an open-source Python package to support reproducibility and collaborative advancement of computational organ viability assessment.

Figure Legends

Figure 2. Hemodynamic pressure profile across hierarchical vascular levels (Section 3.2).

Figure 3. Comparative glomerular filtration rate: CCO v7 baseline vs. v8 calibrated model (Section 3.3).

Figure 4. Mixture of Experts (MoE) architecture and agentic AI workflow (Section 2.7).

Appendix A. Hemodynamic Data — Arterial Tree CCO v8

Table A1. Mean arterial pressure and vessel radius by hierarchical level. Pressures assigned via two-pass calibrated Poiseuille model (k = 0.0132). All 915 bifurcations satisfy Murray's Law (alpha = 3.0, tolerance < 0.5%).

Level	Anatomical correlate	n	R min (μm)	R max (μm)	Mean P (mmHg)
0	Main renal artery	1	500.0	500.0	100.0
1	Segmental arteries	2	388.6	404.8	92.2
2	Lobar arteries	10	271.3	350.5	87.1
3	Interlobar arteries	34	189.9	295.5	81.3
4	Arcuate arteries	72	136.2	242.2	74.6
5	Interlobular arteries	122	104.1	203.3	67.6
6	Afferent arterioles	192	77.0	175.2	60.7
7	Distal afferent arterioles	220	55.5	144.7	55.3
8	Pre-glomerular arterioles	152	50.4	119.5	50.1
9	Terminal arterioles	72	42.3	92.1	48.0
10	Terminal arterioles	24	41.1	68.6	45.1
11	Terminal arterioles	4	47.3	55.0	51.2

905 arterial nodes total. Mean terminal pressure: 58.6 +/- 13.4 mmHg. Physiological floor: 43 mmHg (PBowman + pigc).
